Strange hadron production in O+O collisions at $\sqrt{s_{\rm NN}} = 200 \text{ GeV}$ at STAR

Iris Ponce (Yale) for the STAR Collaboration

Results from high energy collisions of asymmetric small systems (p+Au, p+Pb, etc..), such as flow and enhancement of strangeness production, have generated significant discussions in the field about the initial conditions, including the size of the system, needed to generate a Quark-Gluon Plasma (QGP). A smooth increase in the ratio of strange hadron production to the pion yield as a function of multiplicity has been found in various collision systems (p+p, p+A, A+A). In 2021, STAR collected large datasets with $\sqrt{s_{\rm NN}} = 200$ GeV O+O col-10 lisions at RHIC, a unique symmetric small system collision which allows a more 11 straightforward geometry mapping with centrality than those asymmetric small 12 system collisions like He+Au, or d+Au. This poster will focus on the measured transverse momentum (p_T) spectra, and bulk strange hadron $(\Lambda, \Lambda, \Xi, \Xi, \Omega, \Omega)$ 14 plus pion production in O+O collisions. With the high statistics of the dataset and the extended kinematic coverage benefit from the iTPC upgrade, we can investigate the dependence of strangeness production in O+O oan transverse momentum, centrality, and rapidity.
