The STAR Collaboration at RHIC has measured two-pion correlation functions from p+p collisions at 200 GeV. Spatial scales are extracted via a femtoscopic analysis of the correlations, though this analysis is complicated by the presence of strong non-femtoscopic effects. Our results are put into the context of the world dataset of femtoscopy in hadron-hadron collisions. We present the first direct comparison of femtoscopy in p+p and heavy ion collisions, under identical analysis and detector conditions.

# I. INTRODUCTION AND MOTIVATION

Quantum Chromodynamics (QCD) from numerous direc-

The experimental program of the Relativistic Heavy Ion<sup>110</sup> Collider (RHIC) at Brookhaven National Laboratory probes 

tions. The extraordinary flexibility of the machine permits collisions between heavy and light ions at record energies (up to 200 GeV), polarized and unpolarized protons, and strongly<sub>169</sub>
asymmetric systems such as d+Au. The proton collisions are<sub>170</sub>
the focus of an intense program exploring the spin structure of<sub>171</sub>
the nucleon. However, these collisions also serve as a critical<sub>172</sub>

"baseline" measurement for the heavy ion physics program<sub>173</sub>
 that drove the construction of RHIC.

Studies of ultrarelativistic heavy ion collisions aim to ex-175 117 plore the equation of state of strongly interacting matter. The<sup>176</sup> 118 highly dynamic nature of the collisions, however, does not<sup>177</sup> 119 allow a purely statistical study of static matter as one might<sup>178</sup> 120 perform in condensed matter physics, but rather requires a de-179 121 tailed understanding of the dynamics itself. If a bulk, self-180 122 interacting system is formed (something that should not be as-181 123 sumed *a priori*), the equation of state then plays the dynamic<sup>182</sup> 124 role of generating pressure gradients that drive the collective<sup>183</sup> 125 expansion of the system. Copious evidence [1-4] indicates<sup>184</sup> 126 that a self-interacting system is, in fact, generated in these col-185 127 lisions. The dynamics of the bulk medium is reflected in the186 128 transverse momentum  $(p_T)$  distribution [5, 6] and momentum-<sup>187</sup> 129 space anisotropy (e.g. "elliptic flow") [7, 8] of identified par-188 130 ticles in the soft sector- i.e. at low  $p_T$ . These observables<sup>189</sup> 131 are well-described in a hydrodynamic scenario, in which a190 132 nearly perfect (i.e. very low viscocity) fluid expands explo-191 133 sively under the action of pressure gradients induced by the<sup>192</sup> 134 collision [9]. 135

Two-particle femtoscopy [10] (often called "HBT" anal-194 136 ysis) measures the space-time substructure of the emitting 195 137 source at "freeze-out," the point at which particles decou-196 138 ple from the system [e.g. 11]. Femtoscopic measuresments<sup>197</sup> 139 play a special role in understanding bulk dynamics in heavy<sup>198</sup> 140 ion collisions, for several reasons. Firstly, collective flow<sup>199</sup> 141 generates characteristic space-momentum patterns at freeze-200 142 out that are revealed [11] in the momentum-dependence of<sup>201</sup> 143 pion "HBT radii" (discussed below), the mass dependence 144 of homogeneity lengths [12], and non-identical particle cor-2002 145 relations [13]. Secondly, while a simultaneous description 146 of particle-identified  $p_T$  distributions, elliptic flow and fem-147 toscopic measurements is easily achieved in flow-dominated 148 toy models [e.g. 6], achieving the same level of agreement in 149 a realistic transport calculation is considerably more challeng-150 ing. In particular, addressing this "HBT puzzle" [14] has led<sup>206</sup> 151 to a deeper understanding of the freezeout hypersurface, col-152 lectivity in the initial stage, and the equation of state. Fem-153 toscopic signals of long dynamical timescales expected for 154 a system undergoing a first-order phase transition [15, 16],<sub>207</sub> 155 have not been observed [11], providing early evidence that 156 the system at RHIC evolves from QGP to hadron gas via a 157 crossover [17]. This sensitive and unique connection to im-158 portant underlying physics has motivated a huge systematics 159 of femtoscopic measurements in heavy ion collisions over the 2008 160 past quarter century [11]. 161

HBT correlations from hadron (e.g. p + p) and lepton (e.g.<sup>210</sup>  $e^+ + e^-$ ) collisions have been extensively studied in the high<sub>211</sub> energy physics community, as well [18–20], although the the-<sup>212</sup> oretical interpretation of the results is less clear and well de-<sup>213</sup> veloped. Until now, it has been impossible to quantitatively<sup>214</sup> compare femtoscopic results from hadron-hadron collisions<sup>215</sup> to those from heavy ion collisions, due to divergent and often<sup>216</sup> undocumented analysis techniques, detector acceptances and fitting functions historically used in the high energy community [20].

In this paper, we exploit the unique opportunity offered by the STAR/RHIC experiment, to make the first direct comparison and quantitative connection between femtoscopy in proton-proton and heavy ion collisions. Systematic complications in comparing these collisions are greatly reduced by using identical detector and reconstruction system, collision energies, and analysis techniques (e.g. event mixing [21], see below). We observe and discuss the importance of nonfemtoscopic correlations in the analysis of small systems, and put our femtoscopic results for p + p collisions into the context both of heavy ion collisions and (as much as possible) into the context of previous high-energy measurements on hadronhadron and e - e collisions. We hope that our results may eventually lead to a deeper understanding of the physics behind the space-momentum correlations in these collisions, in the same way that comparison of p + p and heavy ion collision results in the high- $p_T$  sector is crucial for understanding the physics of partonic energy loss [1-4, 22]. Our direct comparison also serves as a model and baseline for similar comparisons soon to be possible at higher energies at the Large Hadron Collider.

The paper is organized as follows. In Section II, we discuss the construction of the correlation function and the forms used to parameterize it. Section III discusses details of the analysis, and the results are presented in Section IV. In Section V, we put these results in the context of previous measurements in Au + Au and elementary particle collisions. We discuss the similarity between the systematics of HBT radii in heavy ion and particle collisions in Section VI and summarize in Section VII.

# II. TWO-PARTICLE CORRELATION FUNCTION

The two-particle correlation function is generally defined as the ratio of the probability of the simultaneous meaurement of measuring two particles with momenta  $p_1$  and  $p_2$ , to the product of single particle probabilities,

$$C(\vec{p}_1, \vec{p}_2) \equiv \frac{P(\vec{p}_1, \vec{p}_2)}{P(\vec{p}_1)P(\vec{p}_2)}.$$
(1)

In practice, one usually studies the quantity

$$C_{\vec{P}}(\vec{q}) = \frac{A_{\vec{P}}(\vec{q})}{B_{\vec{P}}(\vec{q})},$$
(2)

where  $\vec{q} \equiv \vec{p_1} - \vec{p_2}$ .  $A(\vec{q})$  is the distribution of the pairs from the same event, and  $B(\vec{q})$  is the reference (or "background") distribution. *B* contains all single-particle effects, including detector acceptance and efficiency, and is usually calculated with an event-mixing technique [11, 21]. The explicit label  $\vec{P} (\equiv \vec{p_1} + \vec{p_2})$  emphasizes that separate correlation functions are constructed and fitted (see below) as a function of  $\vec{q}$ , for different selections of the total momentum  $\vec{P}$ ; following convention, we drop the explicit subscript below. Sometimes the measured ratio is normalized to unity at large values of  $|\vec{q}|$ ; we<sub>269</sub> include the normalization in the fit. 270

In older or statistics-challenged experiments, the cor-219 relation function is sometimes constructed in the one-220 dimensional quantity  $Q_{inv} \equiv \sqrt{(\vec{p_1} - \vec{p_2})^2 - (E_1 - E_2)^2}$  or 221 two-dimensional variants (see below). More commonly in\_272 222 recent experiments, it is constructed in three dimensions in273 223 the so-called the Pratt-Bertsch "out-side-long" coordinate sys-224 tem [23, 24]. In this system, the "out" direction is that of the 225 pair transverse momentum, the "long" direction is parallel to<sub>275</sub> 226 the beam, and the "side" direction is orthogonal to these two. 227 We will use the subscripts "o," "l" and "s" to indicate quanti-228 ties in these directions. 229

It has been suggested [25–27] to construct the threedimensional correlation function using spherical coordinates

$$q_o = |\vec{q}|\sin\theta\cos\phi, \qquad q_s = |\vec{q}|\sin\theta\sin\phi, \qquad q_l = |\vec{q}|\cos\theta^{280}, \qquad (3)^{281}$$

This aids in making a direct comparison to the spatial sepa-<sup>282</sup> ration distribution through imaging techniques and provides<sup>283</sup> an efficient way to visualize the full three-dimensional struc-<sup>284</sup> ture of  $C(\vec{q})$ . The more traditional "Cartesian projections"<sup>285</sup> in the "o," "s," and "I" directions integrate over most of the three-dimensional structure, especially at large relative momentum [11, 27].

Below, we will present data in the form of the spherical the present data in the form of the spherical harmonic decomposition coefficients, which depend explicitly on  $|\vec{q}|$  as

$$A_{l,m}(|\vec{q}|) \equiv \frac{1}{\sqrt{4\pi}} \int d\phi d(\cos\theta) C(|\vec{q}|,\theta,\phi) Y_{l,m}(\theta,\phi).$$
(4)

The coefficient  $A_{00}(|\vec{q}|)$  represents the overall angle-242 integrated strength of the correlation.  $A_{20}(|\vec{q}|)$  and  $A_{22}(|\vec{q}|)_{_{290}}$ 243 are the quadrupole moments of C at a particular value of  $|\vec{q}|$ . In 244 particular,  $A_{22}$  quantifies the second-order oscillation around<sub>292</sub> 245 the "long" direction; in the simplest HBT analysis, this term,2013 246 reflects non-identical values of the  $R_o$  and  $R_s$  HBT radii (c.f. 247 below). Coefficients with odd l represent a dipole moment 248 of the correlation function and correspond to a "shift" in the 249 average position of the first particle in a pair, relative to the<sub>294</sub> 250 second [25–27]. In the present case of identical particles, the  $_{295}$ 251 labels "first" and "second" become meaningless, and  $odd-l_{296}$ 252 terms vanish by symmetry. Likewise, for the present case,297 253 odd-m terms, and all imaginary components vanish as well.298 254 See Appendix B of [27] for a full discussion of symmetries. 299 255

In heavy ion collisions, it is usually assumed that all of the<sub>300</sub> 256 correlations between identical pions at low relative momen-301 257 tum are due to femtoscopic effects, i.e. quantum statistics and<sub>302</sub> 258 final-state interactions [11]. At large  $|\vec{q}|$ , femtoscopic effects<sub>303</sub> 259 vanish [e.g. 11]. Thus, in the absence of other correlations,  $_{304}$ 260  $C(\vec{q})$  must approach a constant value independent of the mag-<sub>305</sub> 261 nitude and direction of  $\vec{q}$ ; equivalently,  $A_{l,m}(|\vec{q}|)$  must vanish<sub>306</sub> 262 at large  $|\vec{q}|$  for  $l \neq 0$ . 263

However, in elementary particle collisions additional structure at large relative momentum ( $|\vec{q}| \gtrsim 400 \text{ MeV/c}$ ) has been observed [e.g. 20, 28–32]. Usually this structure is parameter-307 ized in terms of a function  $\Omega(\vec{q})$  that contributes in addition to 308

the femtoscopic component  $C_F(\vec{q})$ . Explicitly including the 309

normalization parameter  $\mathcal{N}$ , then, we will fit our measured correlation functions with the form

$$C(\vec{q}) = \mathcal{N} \cdot C_F(\vec{q}) \cdot \Omega(\vec{q}).$$
<sup>(5)</sup>

Below, we discuss separately various parameterizations of the femtoscopic and non-femtoscopic components, which we use in order to connect with previous measurements. A historical discussion of these forms may be found in [20].

### A. Femtoscopic correlations

Femtoscopic correlations between identical pions are dominated by Bose-Einstein symmetrization and Coulomb final state effects in the two-pion wavefunction [11].

In all parameterizations, the overall strength of the femtoscopic correlation is characterized by a parameter  $\lambda$  [11]. Historically misnamed the "chaoticity" parameter, it generally accounts for particle identification efficiency, long-lived decays, and long-range tails in the separation distribution.

In the simplest case, the Bose-Einstein correlations are often parameterized by a Gaussian,

$$C_F(Q_{inv}) = 1 + \lambda e^{-Q_{inv}^2 R_{inv}^2},\tag{6}$$

where  $R_{inv}$  is a one dimensional "HBT radius."

Kopylov and Podgoretskii [33] introduced an alternative, two-dimensional parameterization

$$C_F(q_T, q_0) = 1 + \lambda \left[ \frac{2J_1(q_T R_B)}{q_T R_B} \right]^2 \left( 1 + q_0^2 \tau^2 \right)^{-1}, \quad (7)$$

where  $q_T$  is the component of  $\vec{q}$  orthogonal to  $\vec{P}$ ,  $q_0 = E_1 - E_2$ ,  $R_B$  and  $\tau$  are the size and decay constants of a spherical emitting source, and  $J_1$  is the first order Bessel function. This is similar to another common historical parameterization [e.g. 34] characterizing the source with a spatial and temporal scale

$$C_F(q,q_0) = 1 + \lambda e^{-q_T^2 R_G^2 - q_0^2 \tau^2}.$$
(8)

Simple numerical studies show that  $R_G$  from Eq. 8 is approximately half as large as  $R_B$  obtained from Eq. 7 [20, 34, 35].

With sufficient statistics, a three-dimensional correlation function may be measured. We calculate the relative momentum in the longitudinally co-moving system (LCMS), in which the total longitudinal momentum of the pair,  $p_{l,1} + p_{l,2}$ , vanishes. For heavy ion and hadron-hadron collisions, this "longitudinal" direction  $\hat{l}$  is taken to be the beam axis [11]; for  $e^+ + e^-$  collisions, the thrust axis is used.

For a Gaussian emission source, femtoscopic correlations due only to Bose-Einstein symmetrization are given by [e.g. 11]

$$C_F(q_o, q_s, q_l) = 1 + \lambda e^{-q_o^2 R_o^2 - q_s^2 R_s^2 - q_l^2 R_l^2},$$
(9)

where  $R_o$ ,  $R_s$  and  $R_l$  are the spatial scales of the source.

While older papers sometimes ignored the Coulomb finalstate interaction between the charged pions [20], it is usually included by using the Bowler-Sinyukov [36, 37] functional
 form

$$C_{F}(Q_{inv}) = (1 - \lambda) + \lambda K_{\text{coul}}(Q_{inv}) \left(1 + e^{-Q_{inv}^{2}R_{inv}^{2}}\right), \quad (10)_{349}^{348}$$

315

(

$$C_F(q_o, q_s, q_l) = (1 - \lambda) + \lambda K_{\text{coul}}(Q_{inv})$$

$$\times \left(1 + e^{-q_o^2 R_o^2 - q_s^2 R_s^2 - q_l^2 R_l^2}\right). \quad (11)_{355}^{354}$$

Here,  $K_{\text{coul}}$  is the squared Coulomb wavefunction integrated over the source emission points.

B. Non-femtoscopic correlations

362 In the absence of non-femtoscopic effects, one of the forms  $_{_{363}}$ 316 for  $C_{F}\left( \vec{q}
ight)$  from Section II A is fitted to the measured corre-317 lation function; i.e.  $\Omega = 1$  in Equation 5. Such a "standard<sub>365</sub> 318 fit" works well in the high-multiplicity environment of heavy $_{366}$ 319 ion collisions [11]. In hadron-hadron or e + e collisions, how-320 ever, it does not describe the measured correlation  $\mathrm{function}_{\scriptscriptstyle 368}$ 321 well, especially as |q| increases. Most authors attribute the 322 non-femtoscopic structure to momentum conservation effects 323 in these small systems. While this large-|q| behavior is some-324 times simply ignored, it is usually included in the fit either 325 through ad-hoc [29] or physically-motivated [27] terms. 326

In this paper, we will use three selected parameterizations 327 of the non-femtoscopic correlations and study their effects on the femtoscopic parameters obtained from the fit to experi-329 mental correlation functions. The first formula assumes that 330 the non-femtoscopic contribution can be parameterized by a 331 first-order polynomial in  $\vec{q}$ -components (used e.g. in [38–42]). 332 Respectively, the one- and three-dimensional forms used in 333 the literature are 334 370

$$\Omega(q) = 1 + \delta q \tag{12}^{37}$$

335 and

$$\Omega(\vec{q}) = \Omega(q_o, q_s, q_l) = 1 + \delta_o q_o + \delta_s q_s + \delta_l q_l.$$
(13)

For simplicity, we will use the name " $\delta - q$  fit" when the above formula was used in the fitting procedure.

Another form [43] assumes that non-femtoscopic correla-<sup>375</sup> tions contribute  $|\vec{q}|$ -independent values to the l = 2 moments<sup>376</sup> in Equation 4. In terms of the fitting parameters  $\zeta$  and  $\beta$ , <sup>377</sup>

$$\begin{split} \Omega\left(|\vec{q}|,\cos\theta,\phi\right) &= \Omega\left(\cos\theta,\phi\right) = \\ 1 + 2\sqrt{\pi}\left(\beta Y_{2,0}\left(\cos\theta,\phi\right) + 2\zeta \operatorname{Re}\left[Y_{2,2}\left(\cos\theta,\phi\right)\right]\right) = \\ 1 + \beta\sqrt{\frac{5}{4}}(3\cos^2\theta - 1) + \zeta\sqrt{\frac{15}{2}}\sin^2\theta\cos2\phi. \quad (14)_{_{380}} \end{split}$$

For simplicity, fits using this form for the non-femtoscopic<sub>382</sub> effects will be referred to as " $\zeta - \beta$  fits."

These two forms (as well as others that can be found in literature [20]) are purely empirical, motivated essentially by the shape of the observed correlation function itself. While

most authors attribute these effects primarily to momentum conservation in these low-multiplicity systems, the parameters and functional forms themselves cannot be directly connected to this or any physical mechanism. One may identify two dangers of using an ad-hoc form to quantify nonfemtoscopic contributions to  $C(\vec{q})$ . Firstly, while they describe (by construction) the correlation function well at large  $|\vec{q}|$ , for which femtoscopic contributions vanish, there is no way to constrain their behaviour at low  $|\vec{q}|$  where both femtoscopic and (presumably) non-femtoscopic correlations exist. Even simple effects like momentum conservation give rise to non-femtoscopic correlations that vary non-trivially even at low  $|\vec{q}|$ . Misrepresenting the non-femtoscopic contribution in  $\Omega(\vec{q})$  can therefore distort the femtoscopic radius parameters in  $C_F(\vec{q})$ . Secondly, there is no way to estimate whether the best-fit parameter values in an ad-hoc functional form are "reasonable," given the physics they are intended to parameterize.

If the non-femtoscopic correlations are in fact dominated by energy and momentum conservation, as is usually supposed, one may derive an analytic functional form for  $\Omega$ . In particular, the multiparticle phase space constraints for a system of *N* particles project onto the two-particle space as [27]

$$\Omega(p_1, p_2) = 1 - M_1 \cdot \overline{\{\vec{p}_{1,T} \cdot \vec{p}_{2,T}\}} - M_2 \cdot \overline{\{p_{1,z} \cdot p_{2,z}\}}$$
(15)  
$$- M_3 \cdot \overline{\{E_1 \cdot E_2\}} + M_4 \cdot \overline{\{E_1 + E_2\}} - \frac{M_4^2}{M_3},$$

where

372

373

374

351

352

359

360

361

$$M_{1} \equiv \frac{2}{N \langle p_{T}^{2} \rangle}, \qquad M_{2} \equiv \frac{1}{N \langle p_{z}^{2} \rangle}$$
$$M_{3} \equiv \frac{1}{N (\langle E^{2} \rangle - \langle E \rangle^{2})}, \quad M_{4} \equiv \frac{\langle E \rangle}{N (\langle E^{2} \rangle - \langle E \rangle^{2})}. \quad (16)$$

The notation  $\{X\}$  in Equation 15 is used to indicate that X is a two-particle quantity which depends on  $p_1$  and  $p_2$  (or  $\vec{q}$ , etc). In practice, this means generating histograms in addition to  $A(\vec{q})$  and  $B(\vec{q})$  (c.f. Equation 2) as one loops over pairs in the data analysis. For example

$$\overline{\{\vec{p}_{1,T}\cdot\vec{p}_{2,T}\}}(\vec{q}) = \frac{\sum_{i,j}\vec{p}_{i,T}\cdot\vec{p}_{j,T}}{B(\vec{q})},$$
(17)

where the sum in the numerator runs over all pairs in all events.

In Equation 15, the four fit parameters  $M_i$  are directly related to five physical quantities, (*N* - the number of particles,  $\langle p_T^2 \rangle$ ,  $\langle p_z^2 \rangle$ ,  $\langle E^2 \rangle$ ,  $\langle E \rangle$ ) through Eq. 16. Assuming that

$$\langle E^2 \rangle \approx \langle p_T^2 \rangle + \langle p_z^2 \rangle + m_*^2,$$
 (18)

where  $m_*$  is the mass of a typical particle in the system (for our pion-dominated system,  $m_* \approx m_{\pi}$ ), then one may solve for the physical parameters. For example,

$$N \approx \frac{M_1^{-1} + M_2^{-1} - M_3^{-1}}{\left(\frac{M_4}{M_3}\right)^2 - m_*^2}.$$
 (19)

419

Since we cannot know exactly the values of  $\langle E^2 \rangle$  etc, that characterize the underlying distribution in these collisions, we treat the  $M_i$  as free parameters in our fits, and then consider whether their values are mutually compatible and physical.

In [27], the correlations leading to Equation 15 were called<sub>441</sub>
 "EMCICs" (short for Energy and Momentum Conservation-442
 Induced Correlations); we will refer to fits using this function443
 with this acronym, in our figures. 444

# C. Parameter counting

As mentioned, we will be employing a number of different<sup>449</sup> fitting functions, each of which contains several parameters.<sup>450</sup> It is appropriate at this point to breifly take stock.<sup>451</sup>

In essentially all modern HBT analyses, on the order of<sup>452</sup> 396 5-6 parameters quantify the femtoscopic correlations. For<sup>453</sup> 397 the common Gaussian fit (equation 11), one has three "HBT454 398 radii," the chaoticity parameter, and the normalization  $\mathcal{N}$ .<sup>455</sup> 399 Recent "imaging" fits approximate the two-particle emission<sup>456</sup> 400 zone as a sum of spline functions, the weights of which are the457 401 parameters [45]; the number of splines (hence weights) used<sup>458</sup> 402 is  $\sim$  5. Other fits (e.g. double Gaussian, exponential-plus-<sup>459</sup> 403 Gaussian) [18, 46] contain a similar number of femtoscopic<sup>460</sup> 404 parameters. In all cases, a distinct set of parameters is ex-461 405 tracted for each selection of  $\vec{P}$  (c.f. equation 2 and surrounding<sup>462</sup> 406 discussion). 407

Accounting for the non-femtoscopic correlations inevitably<sup>464</sup> 408 increases the total number of fit parameters. The " $\zeta-\beta$  " func-465 409 tional form (eq. 14) involves two parameters, the " $\delta - q$ " form<sup>466</sup> 410 (eq. 13) three, and the EMCIC form (eq. 15) four. However,467 411 it is important to keep in mind that using the  $\zeta - \beta (\delta - q)^{468}$ 412 form means 2 (3) additional parameters for each selection of 413  $\vec{P}$  when forming the correlation functions. On the other hand, 469 414 the four EMCICs parameters cannot depend on  $\vec{P}$ . Therefore, 415 when fitting  $C_{\vec{P}}(\vec{q})$  for four selections of  $\vec{P}$ , use of the  $\zeta - \beta_{470}$ 416  $\delta - q$  and EMCIC forms increases the total number of param-471 417 eters by 8, 12 and 4, respectively. 418 472

### **III. ANALYSIS DETAILS**

As mentioned in Section I, there is significant advantage476 420 in analyzing p + p collisions in the same way that heavy ion<sub>477</sub> 421 collisions are analyzed. Therefore, the results discussed in this 478 422 paper are produced with the same techniques and acceptance479 423 cuts as have been used for previous pion femtoscopy studies480 424 by STAR [47–50]. Here we discuss some of the main points;481 425 full systematic studies of cuts and techniques can be found482 426 in [49]. 427 483

428 The primary sub-detector used in this analysis to recon-484 struct particles is the Time Projection Chamber (TPC) [51].485 429 Pions could be identified up to a momentum of 800 MeV/c by486 430 correlating their the momentum and specific ionization loss487 431 (dE/dx) in the TPC gas. A particle was considered to be a<sub>488</sub> 432 pion if its dE/dx value for a given momentum was within two<sub>489</sub> 433 sigma of the Bethe-Bloch expectation for a pion, and more<sub>490</sub> 434 than two sigma from the expectations for electrons, kaons and 491 435

protons. The small contamination due to electrons and kaons impacts mostly the value of  $\lambda$  obtained from the fit while it was only a 1% effect of the femtoscopic radii. The lower momentum cut of 120 MeV/c is imposed by the TPC acceptance and the magnetic field. Only tracks at midrapidity (|y| < 0.5) were included in the femtoscopic analysis. Events were selected for analysis if the primary collision vertex was within 30 cm of the center of the TPC. The further requirement that events include at least two like-sign pions increases the average charged particle multiplicity with pseudorapidity  $|\eta| < 0.5$  from 3.0 (without the requirement) to 4.25. Since particle *pairs* enter into the correlation function, the effective average multiplicity is higher; in particular, the pair-weighted charged-particle multiplicity at midrapidity is about 6.0. After event cuts, about 5 million minimum bias events from p + p collisions at  $\sqrt{s}=200$  GeV were used.

Two-track effects, such as splitting (one particle reconstructed as two tracks) and merging (two particles reconstructed as one track) were treated identically as has been done in STAR analyses of Au+Au collisions [49]. Both effects can affect the shape of  $C(\vec{q})$  at very low  $|\vec{q}| \leq 20$  MeV/c, regardless of the colliding system. However, their effect on the extracted sizes in p + p collisions turns out to be smaller than statistical errors, due to the fact that small (~ 1 fm) sources lead to large (~ 200 MeV/c) femtoscopic structures in the correlation function.

The analysis presented in this paper was done for four bins in average transverse momentum  $k_T \ (\equiv \frac{1}{2} | (\vec{p}_{T,1} + \vec{p}_{T,2}) |)$ : 150-250, 250-350, 350-450 and 450-600 MeV/c. The systematic errors due to the fit range, particle mis-identification, two-track effects and the Coulomb radius (used to calculate  $K_{\text{coul}}$  in Eqs. 10 and 11) are estimated to be about 10%, similar to previous studies [49].

## IV. RESULTS

In this section, we present the correlation functions and fits to them, using the various functional forms discussed in Section II. The  $m_T$  and multiplicity dependence of femtoscopic radii from these fits are compared here, and put into the broader context of data from heavy ion and particle collisions in the next section.

Figure 1 shows the two-pion correlation function for minimum-bias p + p collisions for 0.35  $< k_T < 0.45$  GeV/c. The three-dimensional data is represented with the traditional one-dimensional Cartesian projections [11]. For the projection on  $q_o$ , integration in  $q_s$  and  $q_l$  was done over the range [0.00, 0.12] GeV/c. As discussed in Section II and in more detail in [27], the full structure of the correlation function is best seen in the spherical harmonic decomposition, shown in Figures 2-5.

In what follows, we discuss systematics of fits to the correlation function, with particular attention to the femtoscopic parameters. It is important to keep in mind that the fits are performed on the full three-dimensional correlation function  $C(\vec{q})$ . The choice to plot the data and fits as spherical harmonic coefficients  $A_{lm}$  or as Cartesian projections along the "out," "side" and "long" directions is based on the determi<sup>492</sup> nation to present results in the traditional format (projections) <sup>493</sup> or in a representation more sensitive to the three-dimensional <sup>494</sup> structure of the data [27]. In particular, the data and fits shown <sup>495</sup> in Figure 1, for  $k_T$ =0.35-0.45 GeV/c, are the same as those <sup>496</sup> shown in Figure 4.

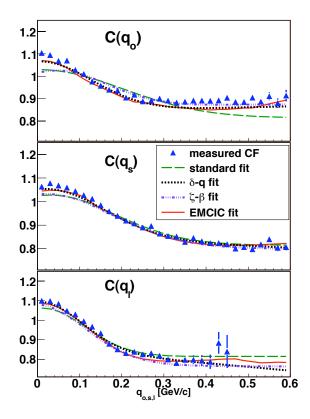

FIG. 1: (Color online) Cartesian projections of the 3D correlation function from p + p collisions at  $\sqrt{s}=200$  GeV for  $k_T = [0.35, 0.45]$ GeV/c (blue triangles). Femtoscopic effects are parameterized with the form in Eq. 11; different curves represent various parameterizations of non-femtoscopic correlations used in the fit and described in detail in Sec. II B.

## 497 A. Transverse mass dependence of 3D femtoscopic radii

Femtoscopic scales from three-dimensional correlation 498 functions are usually extracted by fitting to the functional form514 499 given in Equation 11. In order to make connection to previous<sup>515</sup> 500 measurements, we employ the same form and vary the treat-516 501 ment of non-femtoscopic effects as discussed in Section II B.517 502 The fits are shown as curves in Figures 1-5; the slightly fluctu-518 503 ating structure observable in the sensitive spherical harmonic<sup>519</sup> 504 representation in Figures 2-5 results from finite-binning ef-520 505 fects in plotting [52]. 506

<sup>507</sup> Dashed green curves in Figures 1-5 represent the "standard<sub>522</sub> <sup>508</sup> fit," in which non-femtoscopic correlations are neglected al-<sup>523</sup> <sup>509</sup> together ( $\Omega = 1$ ). Black dotted and purple dashed curves, re-<sup>524</sup> <sup>510</sup> spectively, indicate " $\delta - q$ " (Equation 13) and " $\zeta - \beta$ " (Equa-<sup>525</sup> <sup>511</sup> tion 14) forms. Red curves represent fits in which the non-<sup>526</sup> <sup>512</sup> femtoscopic contributions follow the EMCIC (Equation 15)<sup>527</sup> <sup>513</sup> form. None of the functional forms perfectly fits the ex-<sup>528</sup>

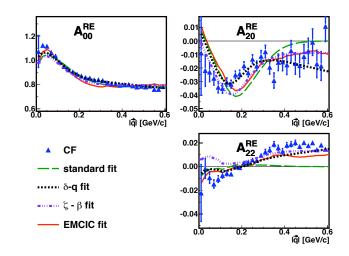

FIG. 2: (Color online) The first three non-vanishing moments of the spherical harmonic decomposition of the correlation function from p + p collisions at  $\sqrt{s}=200$  GeV, for  $k_T = [0.15, 0.25]$  GeV/c. Femtoscopic effects are parameterized with the form in Eq. 11; different curves represent various parameterizations of non-femtoscopic correlations used in the fit and described in detail in Sec. II B.

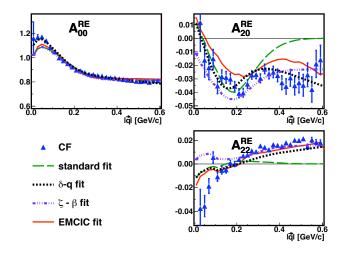

FIG. 3: (Color online) As for Fig. 2, but for  $k_T = [0.25, 0.35]$  GeV/c.

perimental correlation function, though the non-femtoscopic structure is semi-quantitatively reproduced by the ad-hoc  $\delta - q$  and  $\zeta - \beta$  fits (by construction) and the EMCIC fit (non-trivially). Rather than invent yet another ad-hoc functional form to better fit the data, we will consider the radii produced by all of these forms.

The fit parameters for these four fits, for each of the four  $k_T$  bins, are given in Tables I-IV. Considering first the nonfemtoscopic correlations, we observe that the ad-hoc fit parameters  $\delta_{O,S,L}$  and  $\zeta$  and  $\beta$  in Tables III and II are different for each  $k_T$  bin. Due to their physical meaning, the EMCIC parameters  $M_{1-4}$  are fixed for all  $k_T$  values, as indicated in Table IV. Setting the characteristic particle mass to that of the pion and using Equations 16, 18 and 19, the non-femtoscopic parameters listed in Table IV correspond to the following val-

$k_T  [\text{GeV/c}]$	$R_o$ [fm]	$R_s$ [fm]	$R_l$ [fm]	λ
[0.15, 0.25]	$0.84\pm0.02$	$0.89\pm0.01$	$1.53\pm0.02$	$0.422 \pm 0.004$
[0.25, 0.35]	$0.81\pm0.02$	$0.88\pm0.01$	$1.45\pm0.02$	$0.422 \pm 0.005$
[0.35, 0.45]	$0.71\pm0.02$	$0.82\pm0.02$	$1.31 \pm 0.02$	$0.433 \pm 0.007$
[0.45, 0.60]	$0.68\pm0.02$	$0.68\pm0.01$	$1.05\pm0.02$	$0.515 \pm 0.009$

TABLE I: Fit results from a fit to data from p + p collisions at  $\sqrt{s} = 200$  GeV using Eq. 11 to parameterize the femtoscopic correlations ("standard fit").

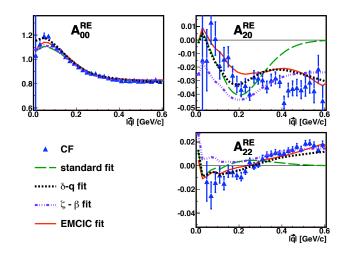

FIG. 4: (Color online) As for Fig. 2, but for  $k_T = [0.35, 0.45]$  GeV/c.

<sup>529</sup> ues characteristic of the emitting system:

$$N = 14.3 \pm 4.7$$
  
 $\langle p_T^2 \rangle = 0.17 \pm 0.06 \; (\text{GeV/c})^2$   
 $\langle p_z^2 \rangle = 0.32 \pm 0.13 \; (\text{GeV/c})^2$   
 $\langle E^2 \rangle = 0.51 \pm 0.11 \; \text{GeV}^2$   
 $\langle E \rangle = 0.68 \pm 0.08 \; \text{GeV}.$ 

<sup>530</sup> These values are rather reasonable [44].

547 HBT radii from the different fits are plotted as a function 531 548 of transverse mass in Figure 6. The treatment of the non-532 femtoscopic correlations significantly affects the magnitude 549 533 of the femtoscopic length scales extracted from the fit, espe-550 534 cially in the "out" and "long" directions, for which variations<sup>551</sup> 535 up to 50% in magnitude are observed. The dependence of 552 536 553 the radii on  $m_T \equiv \sqrt{k_T^2 + m^2}$  is quite similar in all cases. We <sup>554</sup><sub>554</sub> 537 discuss this dependence further in Section V. 538 555

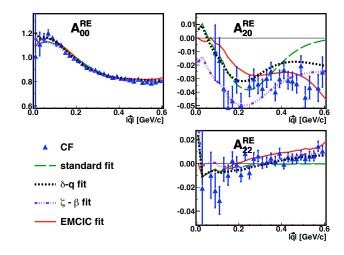

FIG. 5: (Color online) As for Fig. 2, but for  $k_T = [0.45, 0.60]$  GeV/c.

# B. Transverse mass and multiplicity dependence of 1D femtoscopic radii

Since three-dimensional correlation functions encode more information about the homogeneity region than do onedimensional correlation functions, they are also more statistics hungry. Therefore, most previous particle physics experiments have constructed and analyzed the latter. For the sake of making the connection between our results and existing world systematics, we perform similar analyses as those found in the literature.

The first important connection to make is for the  $m_T$ -dependence of HBT radii from minimum-bias p + p collisions. We extract the one-dimensional HBT radius  $R_{inv}$  associated with the femtoscopic form in Equation 10, using three forms for the non-femtoscopic terms. For four selections in  $k_T$ , table V lists the fit parameters for the "stan-dard" fit that neglects non-femtoscopic correlations altogether

$k_T [\text{GeV/c}]$	$R_o$ [fm]	$R_s$ [fm]	$R_l$ [fm]	λ	ζ	β

## 592 V. COMPARISON WITH WORLD SYSTEMATICS

In this section, we make the connection between femto-624 scopic measurements in heavy ion collisions and those in par-625 ticle physics, by placing our results in the context of world 626 systematics from each.

### 597 A. Results in the Context of Heavy Ion Systematics

The present measurement represents the first opportunity to 632 study femtoscopic correlations from hadronic collisions and 633

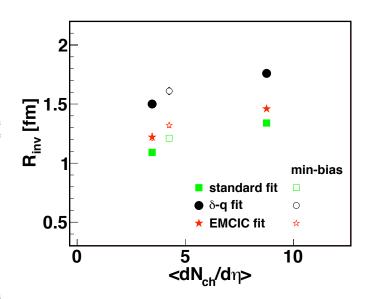

FIG. 8: (Color online) The multiplicity dependence of  $R_{inv}$  from p + p collisions at  $\sqrt{s}=200$  GeV for different parameterizations of the non-femtoscopic correlations. The particles within the range of  $k_T = [0.15, 0.60]$  GeV/c were used in the analysis.

heavy ion collisions, using the same detector, reconstruction, analysis and fitting techniques. The comparison should be direct, and differences in the extracted HBT radii should arise from differences in the source geometry itself. In fact, especially in recent years, the heavy ion community has generally arrived at a consensus among the different experiments, as far as analysis techniques, fitting functions and reference frames to use. This, together with good documentation of event selection and acceptance cuts, has led to a quantitatively consistent world systematics of femtoscopic measurements in heavy ion collisions over two orders of magnitude in collision energy [11]; indeed, at RHIC, the agreement in HBT radii from the different experiments is remarkably good. Thus, inasmuch as STAR's measurement of HBT radii from p + p collisions may be directly compared with STAR's HBT radii from Au+Au collisions, they may be equally well compared to the world's systematics of all heavy ion collisions.

As with most heavy ion observables in the soft sector [53], the HBT radii  $R_s$  and  $R_l$  scale primarily with event multiplicity [11] (or, at lower energies, with the number of particles of different species [54, 55]) rather than energy or impact parameter. The radius  $R_o$ , which nontrivially combines space and time, shows a less clear scaling [11], retaining some energy dependence. As seen in Figure 9, the radii from p + p collisions at  $\sqrt{s}$ =200 GeV fall naturally in line with this multiplicity scaling. On the scale relevant for this comparison, the specific treatment of non-femtoscopic correlations is unimportant.

One of the most important systematics in heavy ion femtoscopy is the  $m_T$ -dependence of HBT radii, which directly measures space-momentum correlations in the emitting source at freeze-out; in these large systems, the  $m_T$ dependence is often attributed to collective flow [6]. As we saw in Figure 6, a significant dependence is seen also for

p + p collisions. Several authors [e.g. 18, 29, 30, 34, 56]<sub>660</sub> 634 have remarked on the qualitative "similarity" of the  $m_{T-661}$ 635 dependence of HBT radii measured in high energy particle662 636 collisions, but the first direct comparison is shown in Fig-663 637 ure 10. There, the ratios of the three dimensional radii in<sub>664</sub> 638 Au+Au collisions to p+p radii obtained with different treat-665 639 ments of the non-femtoscopic correlations, are plotted versus666  $m_T$ . Well beyond qualitative similarity, the ratios are remark-667 641 ably flat–i.e. the  $m_T$ -dependence in p + p collisions is quanti-668 642 tatively almost identical to that in Au+Au collisions at RHIC.669 643 We speculate on the possible meaning of this in Section V B. 670 644

### 645 B. Results in the context of high-energy particle measurements<sup>673</sup> 674

Recently, a review of the femtoscopic results [20] from par-<sup>675</sup> ticle collisions like p + p,  $p + \bar{p}$  and  $e^+ + e^-$  studied at dif-<sup>676</sup> ferent energies has been published. Here, we compare STAR<sup>677</sup> results from p + p collisions at  $\sqrt{s}$ =200 GeV with world sys-<sup>678</sup> tematics.

Figures 11 and 12 compare the multiplicity dependence <sup>680</sup> STAR's one- and two-dimensional fit parameters to hadronic <sup>681</sup> collision data collected in [20]. While any trend in the life-<sub>682</sub> time parameter  $\tau$  is not obvious, radii from each experiment<sub>683</sub> increase with multiplicity. However, in contrast to the "univer-<sub>684</sub> sal" scaling observed in heavy ion collisions (c.f. Figure 9), <sub>685</sub> any such scaling is much more approximate, here.

<sup>658</sup> There are several possible reasons for this [20]. Clearly<sup>687</sup> <sup>659</sup> one possibility is that there is no universal multiplicity de-<sup>688</sup> pendence of the femtoscopic scales; the underlying physics driving the space-time freezeout geometry may be quite different, considering  $\sqrt{s}$  varies from 44 to 1800 GeV in the plot. However, even if there were an underlying universality between these systems, it is not at all clear that it would appear in this figure, due to various difficulties in tabulating historical data [20]. Firstly, as discussed in Section II the experiments used different fitting functions to extract the HBT radii, making direct comparison between them difficult. Secondly, as we have shown, the radii depend on both multiplicity and  $k_T$ . Since, for statistical reasons, the results in Figure 9 are integrated over the acceptance of each experiment, and these acceptances differ strongly, any universal scaling would be obscured. For example, since the acceptance of Tevatron experiment E735 [34] is weighted towards higher  $k_T$  than the other measurements, one expects a systematically lower HBT radius, at a given multiplicity. Indeed, even the "universal" multiplicity scaling in heavy ion collisions is only universal for a fixed selection in  $k_T$ . Thirdly, these experiments did not follow a standard method of measuring and reporting multiplicity; thus the determination of  $\langle dNch/d\eta \rangle$  for any given experiment shown in Figure 9 is only approximate.

From the discussion above, we cannot conclude definitively that there is– or is not– a universal multiplicity scaling of femtoscopic radii in high energy hadron-hadron collisions. We conclude only that an increase of these radii with multiplicity is observed in all measurements for which  $\sqrt{s} \gtrsim 40$  GeV and that the present analysis of p + p collisions is consistent with world systematics.

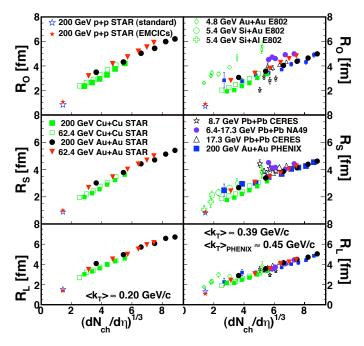

FIG. 9: (Color online) The multiplicity dependence of the HBT radii from p+p, Cu+Cu [50] and Au+Au [49, 50] collisions from STAR compared with results from other experiments [11]. Left and right panels show radii measured with  $\langle k_T \rangle \approx 0.2$  and 0.39 GeV/c, respectively. Radii from p+p collisions are shown by blue ("standard fit") and red ("EMCIC fit") stars.

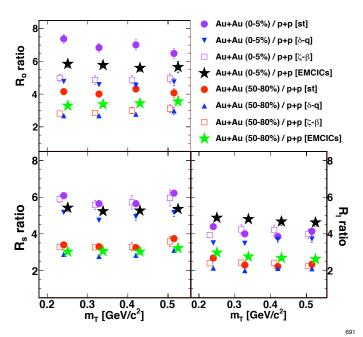

FIG. 11: (Color online) The multiplicity dependence of the 1D femtoscopic radius  $R_{inv}$  from hadronic collisions measured by STAR, E735 [34], and ABCDHW [57] collaborations.

696

high-energy collisions between hadrons– and even leptons– have reported similar trends. As discussed above, direct comparisons with historical high-energy measurements are problematic. Nevertheless, good qualitative and even semiquantitative agreement between fit parameters to 1- and 2dimensional correlation functions is seen in Figures 13 and 14 Indeed, the consistency between the data is impressive, considering that the SPS [29, 40] collisions took place at an order

In Section IV, we discussed the  $p_T$ -dependence of HBT 697 radii observed in our analysis. Previous experiments on 698

729

of magnitude lower in  $\sqrt{s}$ , while the Tevatron data [34] was<sup>727</sup> taken at an order of magnitude higher  $\sqrt{s}$ .

Systematics in 3-dimensional HBT radii from hadron col-730 701 lisions are less clear and less abundant, though our measure-731 702 ments are again qualitatively similar to those reported at the732 703 SPS, as shown in Figure 15. There, we also plot recent results<sub>733</sub> 704 from  $e^+ - e^-$  collisions at LEP; in those 3-dimensional anal-734 705 yses, the "lonngitudinal" direction is the thrust axis, whereas 735 706 the beam axis is used in hadron-hadron collisions, as in heavy 736 707 ion collisions. 737 708

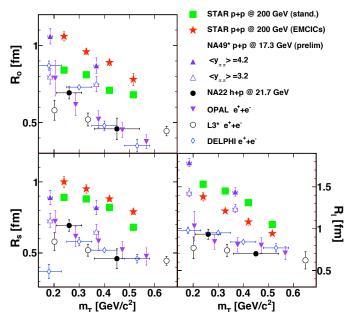

FIG. 15: (Color online) The transverse mass dependence of 3D femtoscopic radii from elementary particle collisions. Data from NA22 [29], NA49 preliminary [61], OPAL [30], L3 [39], DEL-PHI [62].

### VI. DISCUSSION

We have seen that HBT radii from p + p collisions at RHIC are qualitatively consistent with the trends observed in particle collisions over a variety of collision energies. Further, they fall quantitatively into the much better-defined world systematics for heavy ion collisions at RHIC and similar energies. Particularly intriguing is the nearly identical dependence on  $m_T$  of the HBT radii in p + p and heavy ion collisions, as this dependence is supposed [23, 63] to reflect the underlying dynamics of the latter. Several possible sources of an  $m_T$  dependence of HBT radii in small systems have been put forward to explain previous measurements.

1. Alexander *et al.* [64, 65] have suggested that the Heisenberg uncertainty principle can produce the transverse momentum dependence of femtoscopic radii in  $e^+ + e^-$  collisions. However, as discussed in [20], a more detailed study of the results from  $e^+ + e^-$  collisions complicates the quantitative comparisons of the data from various experiments and thus the interpretation. Additionally, Alexander's explanation applies only to the longitudinal direction ( $R_l$ ), so could not explain the dependence of all three radii.

2. In principle, string fragmentation should also generate space-momentum correlations in small systems, hence an  $m_T$  dependence of the HBT radii. However, there are almost no quantitative predictions that can be compared with data. The numerical implementation PYTHIA, which incorporates the Lund string model into the soft sector dynamics, implements HBT only as a crude parameterization designed to mock up the effect [c.f. Section 12.4.3 of 66] for the purpose of estimating distortions to *W*-boson invariant mass spectrum.
Any Bose-Einstein correlation function may be dialed into the
model, with 13 parameters to set the HBT radius, lambda
parameter, and correlation shape; there is no first-principles
predictive power. On more general grounds, the mass dependence of the femtoscopic radii cannot be explained within a
Lund string model [67–69].

3. Long-lived resonances may also generate the space-793 745 momentum dependence of femtoscopic radii [70]. How-794 746 ever, as discussed in [20], the resonances would affect the<sub>795</sub> 747 HBT radii from p + p collisions differently than those from  $_{796}$ 748 Au + Au collisions, since the scale of the resonance "halo" is<sub>797</sub> 749 fixed by resonance lifetimes while the scale of the "core" is<sub>798</sub> 750 different for the two cases. Thus it would have to be a co-749 751 incidence that the same  $m_T$  dependence is observed in both<sub>800</sub> 752 systems. Nevertheless, this avenue should be explored further.801 753

4. Białas *et al.* have introduced a model [67] based on a di-754 rect proportionality between the four-momentum and space-803 755 time freeze-out position; this model successfully described<sub>804</sub> 756 data from  $e^+ + e^-$  collisions. The physical scenario is based<sub>805</sub> 757 on freezeout of particles emitted from a common tube, after<sub>806</sub> 758 a fixed time of 1.5 fm/c. With a very similar model, Hu-807 759 manic [71] was unable to reproduce HBT radii measured at 760 the Tevatron [34] without strong additional hadronic rescat-809 761 tering effects. With rescattering in the final state, both the $_{810}$ 762 multiplicity- and the  $m_T$ -dependence of the radii were repro-763 duced [71]. 764 812

<sup>765</sup> 5. It has been suggested [18, 29, 30, 34, 72] that the  $p_{T^-_{813}}$ <sup>766</sup> dependence of HBT radii in very small systems might reflect<sub>814</sub> <sup>767</sup> bulk collective flow, as it is believed to do in heavy ion colli-<sup>815</sup> sions. This is the only explanation that would automatically <sup>816</sup> account for the nearly identical  $p_T$ -scaling discussed in Sec-<sup>817</sup> tion V A. However, it is widely believed that the system cre-<sup>770</sup> ated in p + p collisions is too small to generate bulk flow.

The remarkable similarity between the femtoscopic system-772 atics in heavy ion and hadron collisions may well be coinci-818 773 dental. Given the importance of the  $m_T$ -dependence of HBT 774 radii in heavy ion collisions, and the unclear origin of this<sub>819</sub> 775 dependence in hadron collisions, further theoretical investiga-820 776 tion is clearly called for. Additional comparative studies of<sub>821</sub> 777 other soft-sector observables (e.g. spectra) may shed further<sub>822</sub> 778 light onto this coincidence. 779 823

# VII. SUMMARY

824

825

826

827

837

838

We have presented a systematic femtoscopic analysis of 828
 two-pion correlation functions from p+p collisions at RHIC.829
 In addition to femtoscopic effects, the data show correlations
 due to energy and momentum conservation. Such effects have
 been observed previously in low-multiplicity measurements at 832

Tevatron, SPS, and elsewhere. In order to compare to historical data and to identify systematic effects on the HBT radii, we have treated these effects with a variety of empirical and physically-motivated formulations. While the overall magnitude of the geometric scales vary with the method, the important systematics do not.

In particular, we observe a significant positive correlation between the one- and three-dimensional radii and the multiplicity of the collision, while the radii decrease with increasing transverse momentum. Qualitatively, similar multiplicity and momentum systematics have been observed previously in measurements of hadron and electron collisions at the SppS, Tevatron, ISR and LEP. However, the results from these experiments could not be directly compared to those from heavy ion collisions, due to differences in techniques, fitting methods, and acceptance.

Thus, the results presented here provide a unique possibility for a direct comparison of femtoscopy in p+p and A+A collisions. We have seen very similar  $p_T$  and multiplicity scaling of the femtoscopic scales in p+p as in A+A collisions, independent of the fitting method employed. Given the importance of femtoscopic systematics in understanding the bulk sector in Au + Au collisions, further exploration of the physics behind the same scalings in p + p collisions is clearly important, to understand our "reference" system. The similarities observed could indicate a deep connection of the underlying bulk physics driving systems much larger than- and on the order of- the confinement scale. Similar comparisons will be possible at the Large Hadron Collider, where the higher collision energies will render conservation laws less important, especially for selections on the very highest-multiplicity collisions.
